Abstract*

Latin American countries have long exhibited low levels of saving rates when compared to other countries in relatively similar stages of economic development (e.g., Asian economies). Motivated by this fact, this paper examines the time path of the saving rates between 1970 and 2010 in three Latin American countries—Chile, Colombia, and Mexico—through the lens of the neoclassical growth model. The findings indicate that two factors, the TFP growth rate and fiscal policy (via tax rates and government expenditure), are capable of accounting for some of the major fluctuations in saving rates observed in these years. For instance, the impressive increase in Chile's saving rate following the early 1980s debt crisis is likely to have resulted from a combination of high TFP growth and a tax reform that substantially reduced capital taxation. Counterfactual experiments also reveal that average saving rates in Latin America could have been some three percentage points higher, had the region experienced TFP growth similar to that of the Asian countries. This increase, however, is insufficient to bridge the observed gap between saving rates in the two regions.

1 Introduction

Latin American countries have long exhibited low saving rates when compared with other countries in similar stages of economic development. Figure 1 displays the average saving rate among the largest six Latin American countries (Argentina, Brazil, Chile, Colombia, Mexico, and Peru) and compares it with that of five Asian countries (China, Korea, Singapore, Hong Kong, and Taiwan) between 1970 and 2010. During this time, the average gross national saving rate (GNSR) in this group of Latin American countries was 18.9%, nearly half that of the Asian countries, 35.5%. Simultaneously, the differences in terms of economic performance across the two regions has been striking. While average GDP per capita in these Latin American countries, as a share of US GDP per capita, increased only from 21% to 31% between 1970 and 2014, that of the five Asian countries went from from 18% to 83%.

What accounts for the anemic saving rates in Latin America? To what extent have they been related to the forces that have shaped economic growth in the region? We address these questions in this paper by making use of neoclassical growth theory. We build a one-sector, neoclassical growth model and calibrate it to a subset of Latin American economies. A crucial element in the calibration is to use (and in some cases construct from primary sources) a time series of the forces that have driven economic growth in these countries for the past 40 years. In particular, we examine the role of total factor productivity (TFP) growth, tax rates, size of the government, and population growth rate for these countries between 1970 and 2014. With the calibrated model, we then conduct deterministic simulations taking the actual capital stock in 1970 as an initial condition in each country, and the actual time paths of each of the exogenous factors to derive the saving behavior as predicted by the model (as well as other key variables such as capital and labor) and compare it to its counterpart in the data. Insofar as the model-based saving

¹Data on the gross national saving rates are from the World Bank's World Development Indicators. Furthermore, using data from the IMF's World Economic Outlook, the six Latin American countries account for 85.9% of the region's 2015 total GDP in USD (from a total of 17 Latin American economies).

²The GNSR is defined as one minus the ratio of final consumption expenditure to gross national income. The computation of gross saving rates is far easier and more transparent (than, say, net saving rates), which makes it more amenable to cross-country comparisons. Moreover, we concentrate on the gross rate since we lack reliable data on depreciation, which we would need in our simulations below if we were to define saving in net terms. Likewise, we focus on the national rather than the domestic saving rate so as to be consistent with the closed-economy nature of the model used below.

³The same difference results when medians are used. Median GDP per capita in these Latin American countries, as a share of US GDP per capita, increased from 17% to 30% between 1970 and 2014, and that of the five Asian countries went from 20% to 85%. Numbers come from Penn World Tables (version 9.0).

rates resemble the data, we can run counterfactual experiments where each of the driving forces is explored in isolation in order to assess its relative importance when accounting for the observed savings. A final experiment that we do is to counterfactually introduce driving forces from the above-mentioned Asian countries, and assess the extent to which differences in these driving forces can account for the different behavior of saving rates across regions.

The subset of Latin American countries that we study closely in this paper are Chile, Colombia, and Mexico. We focus on these three countries for tractability and because they appear to be representative of the Latin American region. The average saving rate across the three countries between 1970 and 2014 is 18%, virtually identical to that of the larger pool of Latin American depicted in Figure 1. At the same time, while these countries have similar average saving rates for the overall period –17.6% in Chile, 16.4% in Colombia, and 19.9% in Mexico—, there are marked differences in their time paths, thus providing enough variability to assess how alternative forces have played different roles through time. For example, the saving rate in Chile was initially lower than the saving rates in Colombia and Mexico. After the mid 1980s, savings in Chile increases while saving rates in Mexico and Colombia decrease to reverse the earlier patterns. In fact, the saving rate in Chile triples between 1985 and 1988, rising from 8% to 24%. During the same time, the saving rate in Mexico declines from 23% to 21%, while it increases slightly in Colombia.

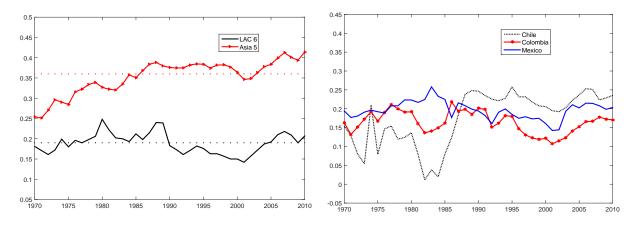

Figure 1: Gross National Saving Rate

Note: The left panel presents the simple average of GNSRs across six Latin American countries (LAC6) –Argentina, Brazil, Chile, Colombia, Mexico, and Peru– in solid/black; and across five South East Asian countries (Asia 5) –China, Korea, Singapore, Hong Kong, and Taiwan– in red with markers. The right panel presents the gross national saving rates across a subset of the Latin American countries –Chile, Colombia, and Mexico–. Source: World Bank's WDI.

Our findings indicate that two factors, TFP growth and fiscal policy (tax rates and the share of government expenditures), are capable of accounting for some of the major changes in the time path of the observed saving rates in Chile and Colombia. The model accounts for the low saving rates in Chile compared to Colombia until the late 1980s and the reversal in the saving rates after that period while also accounting for the behavior of capital and labor observed in the data. Both the fiscal policy and the TFP growth rate behave quite differently throughout this time period between these two countries. The tax rates that we construct point to a dramatic decline in the corporate tax rate in Chile from over 50 percent until 1986/87 to around 10% afterward. Available evidence (Hsieh and Parker, 2007; Cerda et al., 2015) confirms this strong decline of tax rates in Chile. In Colombia, on the other hand, the average tax rate increases from 3.8% to 7.9% after 1987. While the tax rates are low in Colombia, the share of government expenditures increases, reaching 17% at the end of this time period. In Chile, on the other hand, the share of government expenditure declines from an average of 15% before 1987 to 12% afterward. TFP growth rates in Chile and Colombia also start diverging after 1987. The average annual TFP growth rate between 1970 and 1987 is 1.3% in Colombia and 1.8% in Chile. Between 1989 and 2010, on the other hand, the average TFP growth rate increases to 2.5% in Chile while it declines to 1% in Colombia. The decline in the tax rate and the higher rate of TFP growth contribute to the increase in the saving rate in Chile after 1989, leading to the divergence in the saving rates between the two countries.

While the model's performance is weaker for Mexico, there are interesting insights learned from the comparison between Mexico and Chile as well. For example, both Mexico and Chile reform their tax systems in 1987. Yet, while the saving rate triples in Chile between 1985 and 1989, it actually declines in Mexico. This observation is not puzzling in light of our findings. It turns out that the behavior of another factor that affects saving rates is very different between the two countries between 1985 and 1989. The average TFP growth rate in Mexico is -4% during this time period while it is 4.5% in Chile. High growth rate of productivity results in high returns to capital, incentivizing higher savings. Thus, in Chile, the reduction in the tax rate that coincides with a higher TFP growth rate results in a spectacular increase in the saving rate.

We also examine if differences in TFP growth rates between the Asian and Latin American countries can account for the differences in their saving rates. In particular, we run a counterfactual experiment where we investigate how much the saving rates of the Latin American countries would have increased had they been exposed to the much faster TFP growth experienced by Asian economies. Our findings indicate that while the counter-

factual saving rates increase, they are still far from those observed in Asian economies. Therefore, lower productivity growth rates experienced in the Latin American countries relative to those in Asia are unlikely to be responsible for the large and persistent differences in the saving rates between these two regions. This is in line with recent research, for example, about China that highlights alternative explanations other than high TFP growth that account for the high observed saving rates including income uncertainty, lack of comprehensive pension coverage, lack of long-term-care insurance, and the decline in family insurance due to the one-child policy. Differences in these dimensions may account for most of the differences in saving rates across these regions. A more comprehensive study of these issues is left for future work.

Two strands of the literature are perhaps the most relevant for this paper. First, our methodological approach follows recent research aimed at using neoclassical growth theory to study macroeconomic phenomena as best exemplified in the volume edited by Kehoe and Prescott (2007) that aims at accounting for large economic downturns. The work by Bergoeing et al. (2002) in that volume is closely related to ours as they compare the differences in economic performance between Chile and Mexico before and after the debt crises of the 1980s. They argue that Chile recovered much faster than Mexico after the debt crises due to its earlier policy reforms that generated faster productivity growth. Unlike this research, however, they do not study the differences in saving rates across the two countries. Chen, Imrohoroglu, and Imrohoroglu (2006) use the same methodological approach by calibrating a neoclassical growth model to study the behavior of saving rates but focus only on Japan during the second half of the twentieth century. To the best of our knowledge, this is the first paper to use such an approach to study the dynamics of saving rates in Latin America.

Our work relates also to earlier studies that have analyzed the saving rates in Latin America, although from alternative methodological frameworks. Some works, for example, focus on the role of the saving rates in Chile relative to Mexico in facilitating high growth. The spectacular increase in the saving rate in Chile in the late 1980s is attributed to sustained growth of GDP in Morande (1998), higher total factor productivity and higher public savings in Holzmann (1997), and financial reforms and implementation of mandatory fully funded pension systems in Rodrik (2000). The Chilean experience has often been suggested as a path to prosperity for other Latin American countries. Low saving rates in

⁴See for example, Chamon, Liu, and Prasad (2013); Curtis, Lugauer, and Mark (2015); He, Ning, and Zhu (2015); Choukhmane, Coeurdacier, and Jin (2013); Wei and Zhang (2011); and Imrohoroglu and Zhao (2016).

Latin America have been a source of concern in Edwards (1996); Loayza, Schmidt-Hebbel, and Serven (2000); and Grigoli, Herman, and Schmidt-Hebbel (2015) while high saving rates in Asia have been hailed as an important factor in their economic growth (Stiglitz, 1996). Policies geared toward increasing the saving rate for Latin American countries have been suggested by De La Torre and Ize (2015) and Cavallo and Serebrisky (2016), among others. We contribute to this literature by investigating the endogenous response of the saving rate to changes in productivity and fiscal policy. Our results indicate that both of these factors have an important role to play in shaping the time path of the saving rate.

The remainder of the paper is as follows. Sections 2 and 3 present the neoclassical model used and its calibration. The main results of the paper are gathered in Section 4, including the various counterfactual experiments that we undertake. Section 5 concludes. Further technical details are gathered in an Appendix at the end.

2 The Model

We use a simple version of the one-sector neoclassical model (e.g., Cass, 1965; Koopmans, 1965). In this model, there is a stand-in household with N_t working-age members at date t. This representative household decides on labor, consumption, and capital accumulation so as to maximize lifetime utility subject to resource and technological constraints. Formally, the household's objective function is:

$$\max \left\{ \sum_{t=0}^{\infty} \beta^t N_t \left[\log c_t + \alpha \log \left(T - h_t \right) \right] \right\},\,$$

where $N_{t+1}/N_t = n_t$ is the growth of the household size, $c_t = C_t/N_t$ and $h_t = H_t/N_t$ are per capita consumption and labor choices, T is the total endowment of hours per household, β is the subjective discount factor, and α is the share of leisure in the utility function. Technology takes the form of a constant return to scale production function that combines capital (K_t) and labor (H_t) inputs: $Y_t = A_t K_t^{\theta} H_t^{1-\theta}$, where A_t is a measure of TFP. Agents' choices are thus subject to the resource constraint:

$$C_t + X_t \le w_t H_t + \left[r_t - \tau_t \left(r_t - \delta_t \right) \right] K_t + \pi_t$$

where X_t is investment, r_t is the rental rate of capital, τ_t is the tax rate on capital returns, δ_t is capital depreciation, and π_t is a lump-sum tax that is used to ensure that the government budget constraint is satisfied each period: $G_t - \tau_t (r_t - \delta_t) K_t = \pi_t$; with G_t denoting

exogenous government consumption. The economy-wide resource constraint is given by $C_t + X_t + G_t = Y_t$, where X_t enters the capital law of motion as:

$$X_t = K_{t+1} - (1 - \delta_t) K_t \tag{1}$$

The optimal saving decisions by households will be determined by the exogenous driving forces, namely the growth rate of the productivity (TFP) factor, $\gamma_t = (A_{t+1}/A_t)^{1/(1-\theta)}$, as well as G_t , τ_t , n_t , and δ_t through the way they affect the standard equilibrium conditions that include a labor supply equation, the resource constraint, and the Euler equation:

$$\frac{\tilde{c}_{t+1}}{\tilde{c}_t} = \frac{\beta}{\gamma} \left\{ 1 + (1 - \tau_{t+1}) \left[\theta \left(\frac{\tilde{k}_{t+1}}{h_{t+1}} \right)^{\theta - 1} - \delta_{t+1} \right] \right\}$$
 (2)

where $\tilde{c}_t = C_t A_t^{1/(\theta-1)}/N_t$ and and $\tilde{k}_t = K_t A_t^{1/(\theta-1)}/N_t$ are de-trended values of C_t and K_t . When calibrating the model as well as when comparing its performance against the data we will work with the gross national saving rate, formally defined as:

$$s_t = \frac{Y_t - G_t - C_t}{Y_t}$$

3 Calibration and Mesurement

We calibrate the neoclassical model of the previous section for three Latin American countries: Chile, Colombia, and Mexico. Results are summarized in Table 1. In all cases, the capital share in production, θ , is set to 0.3, and the depreciation rate, δ , is set to 0.035. The remaining parameters are calibrated so as to match certain features of the country-specific data for the period 1970-2010. Data for saving (GNSR), household and government consumption, working age population, and gross national product are taken from the World Bank's World Development Indicators (WDI). Total annual hours worked are taken from the Conference Board Total Economy Database.

 $^{^5 \}text{The value} \ \alpha = 0.3$ is also used in previous growth accounting work for Chile and Mexico (Kehoe and Meza, 2011; Bergoeing et al., 2002). Our value $\delta = 0.035$ is lower than that used in the latter studies (which is closer to 5%) but corresponds to the average annual depreciation rate for 1960-2013 used by Chile's Potential GDP Advisory Council of the Ministry of Finance (DIPRES, 2016) in its growth accounting exercises, and is very close to the average of Colombia's Central Bank estimate for the 1950-96 period (GRECO, 2002).

	Table 1: Baseline Calibration								
Parameter	Description	Mexico	Chile	Colombia					
β	Discount factor	0.946	0.960	0.933					
heta	Capital share	0.3	0.3	0.3					
α	Disutility of labor	3.1	3.4	3.2					
δ	Depreciation rate	0.035	0.035	0.035					
K/Y	Capital-output ratio	1.95	2.45	2.5					
Steady-state									
γ	Productivity growth	1.001	1.020	1.014					
g	Government share	0.107	0.130	0.170					
n	Population growth	1.020	1.011	1.014					
au	Tax rate on capital	0.084	0.120	0.080					

Note: The upper panel reports the values for the parameters used in the calibration of the benchmark neoclassical growth model for each of the three countries considered –Chile, Colombia, and Mexico–. The lower panel presents the steady state values for the four driving forces considered in the benchmark model.

A crucial step in our calibration of the model is to obtain an adequate measure of the capital stock. In doing so, we follow Hayashi and Prescott (2002) and include the current account balance in investment. Thus, while we do not model the rest of the world explicitly, our capital stock series include claims of the rest of the world. More precisely, we first use data on investment and inventories along with equation (1) to construct a series of total capital in the economy. To this we add net foreign assets from the External Wealth of Nations (Lane and Milesi-Ferretti, 2007) database to obtain a measure of national capital. This measure is then used along with GNP and hours worked to obtain a series of total factor productivity (TFP).

Another critical input in our quantitative exercise is a measure of effective capital tax rates. For Colombia, we are able to construct a time series of such rates following Mendoza, Razin, and Tesar (1994) using data from national sources. However, such data are partially available in Chile only for the years 1996-2010 and in Mexico only for the 1993-2010 period. For the missing years we follow Bergoeing et al., 2002 in assuming a constant tax rate of 41% in Mexico and 56% in Chile during the period 1970-1987 and then in 1988 let the rate fall to the first value computed using national sources (10.1% in Mexico and 11.2% in Chile). Hsieh and Parker (2007) and Cerda et al. (2015) present compelling evidence that corporate tax rates were lowered by these approximate magnitudes around 1987-88

⁶In Bergoeing et al. (2002), the tax rate falls permanently in 1988 to 10% in both countries.

in Chile while Urzua (2000) documents that a considerable corporate tax reform also took place in Mexico around the same time.⁷

To calibrate the remaining model parameters, we proceed as follows. The discount factor is chosen so that, given the other parameter choices, we can approximate the model's steady state gross savings rate to the average empirical counterpart in each country. 8 Next, the labor elasticity parameter, α , is set so as to match the corresponding average weekly hours worked per household. Finally, the initial capital-to-output ratio is used to approximately pin down the initial saving rate observed in the data.

We use a shooting algorithm to numerically compute the equilibrium transition path of the endogenous macroeconomic aggregates generated by the model as it converges to a final steady state. This, however, requires us to take a stand on what the steady state values are for the exogenous variables: TFP factor growth, population growth, government spending, and capital taxes. For steady state government spending, we use the period average for Chile and Mexico. In the case of Colombia, we use the average for the 1991-2010 sub-period instead, since the 1991 constitutional change resulted in a large –and rather permanent—shift in government spending. For the TFP growth factor, we use the period average in Colombia and Chile; in the case of Mexico, we use the post-1990 average since the average for the entire period is negative, which prevents convergence of the algorithm. The steady state rate of capital taxation in Colombia corresponds to the post-1991 average (again due to a large permanent increase observed after the constitutional change), while for Chile and Mexico, we use the post-reform (i.e., post-1988) average. For (working age) population growth in all three cases, we use the last available value from the WDI (2014).

Figure 2 displays the four driving forces for each of the three countries considered.¹⁰ There are significant similarities and differences between the countries in these exogenous factors. It is evident from the first panel that TFP in Chile grew much faster than in

⁷An important reason for focusing on these three Latin American countries is that serious limitations exist for other countries in this region in terms of the data required for a proper calibration of the model, particularly related to long time series data on effective tax rates.

⁸The model's steady state GNSR is defined as $s = \frac{(\gamma n - 1)k}{y}$ where k and y are the (detrended) steady state values of capital and income. The average empirical counterparts for the saving rates are: 17.6% in Chile, 16.4% in Colombia, and 19.7% in Mexico. Note that we use different discount factors to match the steady state saving rates in each country. From equation (2) it can be seen that, since both β and τ affect the capital accumulation decision, these results could also be obtained by using an identical discount factor for all countries but different capital "wedges" that can possibly account for mismeasurement in our capital tax rates or other distortions to the accumulation of capital.

⁹The average weekly hours worked from the Conference Board Total Economy Database are: 22.5 in Chile, 23.4 in Colombia, and 24.5 in Mexico.

¹⁰We present the evolution of the TFP factor in levels merely to facilitate comparison, but notice that it is its growth rate, not level, that enters the model's equilibrium equations.

Colombia and Mexico, leading to a higher level of TFP by the mid-1980s. Tax rates were much higher in Chile and Mexico compared to Colombia and were lowered significantly in the mid 1980s. The share of government consumption in GNP fell in Chile in the mid-1980s, while it increased in Mexico and more so in Colombia after the new constitution in 1991. Population growth rates fell in all the countries after the mid-1980s, with Chile displaying the lowest levels overall.

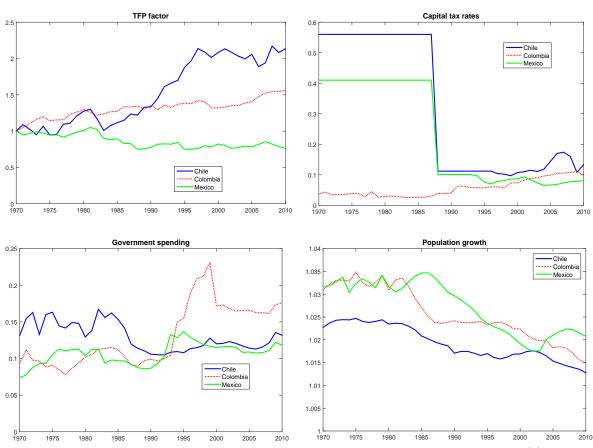

Figure 2: Four Driving Forces

Note: The four plots present the time series for each of the four driving forces considered –TFP growth (γ) , capital tax rate (τ) , government spending (G_t/Y_t) , and population growth rate (n_t) – when simulating/calibrating the benchmark neoclassical growth model across the three Latin American countries considered –Chile, Colombia, and Mexico–. See text and appendix for details and sources used in each driving force.

4 Results

4.1 Benchmark Results

Figure 3 presents the simulated GNSR in Colombia, Chile, and Mexico between 1970 and 2010 generated with our benchmark economies when time series data for all five driving forces—the tax rate, the share of government consumption in GNP, and the growth rates of the TFP factor and population— are fed into the calibrated models. Figure 3 also displays the observed GNSR in the three countries so a comparison of the model's ability to account for the actual behavior of saving rates can be made. Further evidence of the model's performance in terms of capturing other dynamics in the data is presented in Figure 4, where we report the model's generated hours worked and capital-to-output ratio together with their data counterparts for the three countries.¹¹

Saving rate: Chile Saving rate: Colombia Saving rate: Mexico 0.3 0.3 0.25 0.25 0. 0.15 0.05 0.1 -0.1 0.05 2000 2005 2010 1970

Figure 3: Saving Rate: Model and Data

Note: The plots present the observed gross national saving rate ("data," blue/solid) and the simulated one using the calibrated benchmark neoclassical model ("model," red/dashed) when all four driving forces are used for the three Latin American countries considered –Chile, Colombia, and Mexico–. Sources: World Bank's WDI and authors' calculations.

The main takeaway from Figure 3 is the relatively good performance of the model in terms of its ability to account for both the level as well as the broad dynamics of the saving rates observed during the 40 year period of analysis, particularly in the cases of Chile and Colombia. For the case of Chile, the model captures the dramatic increase in the saving rate in the mid-1980s and its decline in the previous years. Similarly, for Colombia, the model captures the decline from around 15%-20% from 1970 until the mid-1990s to around 10% in the early 2000s as well as its subsequent recovery. In the case of Mexico, the performance of the model is relatively weaker, as the simulated saving rates display more

¹¹These relative differences in the performance of the model can be seen in the correlations between the data and the model-generated saving rates: 0.70 for Chile, 0.75 for Colombia, and 0.42 for Mexico.

short-run fluctuations than are observed in the data. Nonetheless, the model does account for the long-run trends in the Mexican saving rate: an increase in the first years of the sample up to the early 1990s followed by a decline until the early 2000s and a recovery since then.

Figure 4 also documents the calibrated model's ability to account for part of the dynamics of the inputs used in production, capital, and labor. For Chile, the model accounts for the relative increase of labor in the second half of the sample as well as the U-shaped path of the capital-to-output ratio across the 40 years of analysis. In Colombia, the model can replicate the behavior of labor in the second half of the sample and the gradual accumulation of capital's share until the 2000s, when the trend reverses. For Mexico, again, the performance of the model is more modest, capturing only the upward trend in the capital-to-output ratio throughout the sample.

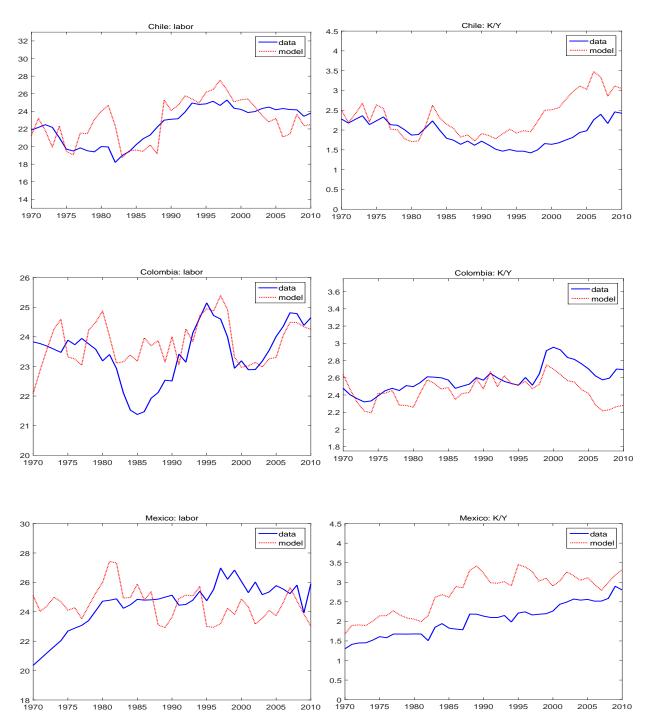

There are, nonetheless, some dynamics that the simulated time series exhibit that are counterfactual. In terms of the saving rates, the model displays relatively larger fluctuations than in the data. This is particularly the case for Mexico, though it also holds for the other two countries. ¹² In addition, the model generates a declining saving rate in the late 2000s for Chile, while in the data we observe a steady saving rate. In Colombia, the model generates a sharp decline in the saving rate in 1999 that is not observed in the data.

In terms of capital and labor inputs, in the early years, the model-generated hours worked misses some of the major changes observed in the data in Chile and Colombia. For example, hours worked declines dramatically in Colombia in the mid-1980s, and the model is not able to capture this. In Chile, the model implied hours worked increases significantly in the late 1970s while in the data hours worked remain stable. For Mexico, neither the level nor the dynamics of hours worked are well captured by the model, and the level of the capital-to-output ratio is not properly matched.

There are, of course, multiple reasons for the discrepancies between the model generated results and the data. The model's counterfactually high volatility is likely to be a consequence of the perfect foresight assumption as discussed in Chen, Imrohoroglu, and Imrohoroglu (2006). In addition, there are potential measurement issues that are likely to

¹²A statistic that summarizes this behavior is the ratio of standard deviations from the simulated series and the data. This number is 1.52 for Chile, 1.54 for Colombia, and 1.91 for Mexico. In other words, the standard deviation of the simulated series in Mexico is 91% higher than that of the observed series.

Figure 4: Labor and Capital: Model and Data

Note: The plots present the time series for labor, measured in hours per week, in the left column, and capital-to-output shares in the right column from the data ("data," blue/solid) and the simulated one using the calibrated benchmark neoclassical model ("model," red/dashed) when all four driving forces are used, for the three Latin American countries considered –Chile, Colombia, and Mexico–. Sources: World Bank's WDI, Conference Board Total Economy Database, and authors' calculations.

impact the TFP series obtained from the data.¹³ We also have not incorporated any lifecycle reasons for savings such as the changes in the social security system that happened during this time period in Chile or changes that may have taken place in other social insurance programs. Our framework presents an attempt to understand how the national saving rate is affected by three simple factors: changes in demographics, the size of the government, and the growth rate of productivity. In the next section, we investigate the role these different factors play in generating the benchmark results by running a set of counterfactual experiments.

4.2 Counterfactuals

In this section, we present a set of counterfactual experiments to isolate the exogenous factors' impact on the saving rate time path in each country. We focus on the two countries –Chile and Colombia– where the performance of the model is satisfactory in accounting for the observed dynamics of saving rates. We investigate the role of the productivity growth rate by setting all exogenous variables except the TFP growth rate equal to their long-run averages. This experiment allows us to isolate the impact of productivity growth on the saving rate. Next, we examine the role of changing demographics by setting all exogenous variables except the population growth rate equal to their long-run averages. Lastly, we examine the role of fiscal policy by only allowing G/Y and tax rates to change as they did in the data while we set the TFP and population growth rates equal to their long-run averages. 15

Our findings indicate a small impact of the change in demographics on the time path of the saving rate. Therefore, we present those results in the Appendix. The main question that remains is the role of productivity growth versus fiscal policy in accounting for the changes in the saving rate. That is what we examine in detail for each country next.

¹³Note that we do not adjust the capital input for variable capacity utilization when constructing our measures of TFP. Nonetheless, for the countries (and years) for which data on capacity of capital utilization rates exist –Chile (1970-2010) and Colombia (1980-2010) — we provide evidence in the Appendix that results are strongly robust when one does account for this additional dimension. Indeed, TFP growth rates with and without capacity utilization rates are strongly correlated in both Chile (0.98) and Colombia (0.85) for the subperiods mentioned above.

¹⁴The results of the counterfactuals for Mexico are, nonetheless, presented in the Appendix. They suggest that a possible culprit for the model's poor performance is an overly volatile TFP series, which in turn may be a symptom of poorly measured production inputs (capital and labor).

¹⁵Note that looking at G/Y and tax rates separately implies additional changes in π_t , the a lump-sum tax that is used to ensure that the government budget constraint is satisfied. Given the large changes in G/Y, we think it is appropriate to consider both driving forces to be active at the same time when studying the effects of fiscal policy.

4.2.1 Chile

In the left panel of Figure 5, labeled "Chile:TFP only," we present the model generated saving rate for Chile when the only time-series path used in the simulations is the TFP factor growth rate. All other factors are set to their long-run averages. For comparison, the saving rate generated by the benchmark economy and the data are also included in the same graph. The saving rate obtained in this counterfactual reveals some interesting observations. First, for many periods, the saving rate generated in this counterfactual resembles the one in the benchmark economy. In particular, the fluctuations observed in the saving rate seem to be mostly due to the changes in the growth rate of the TFP factor. Indeed, the saving rate with "TFP only" seems to generate some of the major changes in the saving rate. For example, between 1980 and 1982, the saving rate in Chile declines from 13.6% to 1.1%. The counterfactual experiment "TFP only" does indeed generate a large decline in the model as well, albeit too large compared to the data. The observed growth rate of the TFP factor declines from 2.3% in 1980 to -13.7% in 1982. This decline alone seems to generate a large decrease in the saving rate in that period. In fact, it is useful to compare the results generated by the alternative counterfactual experiment displayed in the right panel of Figure 5, labeled "Chile: Fiscal policy only". In this case, TFP factor growth rate is set to its long-run average while the actual G/Y and tax rates that are observed in the data are used in the simulations. Notice that in this counterfactual experiment there is no decline in the saving rate between 1980 and 1982. Thus, between the two exogenous forces, our results identify the TFP growth rate as the culprit behind the decline in the saving rate between 1980 and 1982 in Chile.

Another dramatic change in the saving rate takes place between 1984 and 1988 where the observed saving rate increases from 2% to 24%. In our first counterfactual experiment, "TFP only," there is an increase in the saving rate that starts in 1983, but the increase is much more subdued compared to the data. For example, in 1988, the model-generated saving rate with "TFP only" generates a saving rate of about 9%. In the second counterfactual experiment, "fiscal policy only," the saving rate does indeed show a dramatic increase, reaching 33% by 1988. The actual timing of the increase, however is later than in the data. In the model, the tax reform takes effect in 1987, which is why the saving rate in this counterfactual experiment increases dramatically after that year. The gradual increase in the saving rate observed in the benchmark economy after 1983 and before the tax reform, is therefore due to the increase in the productivity growth rate.

Figure 5: Saving Rate in Chile: Counterfactual Experiments

Note: The left plot compares the observed gross national saving rate in Chile ("data," blue/solid) against the counterfactual case in which the only driving force that is active when simulating the model is the TFP growth rate and the remaining three driving forces are set equal to their steady state levels ("TFP only," red/marker). The right plot compares the observed gross national saving rate in Chile ("data," black/solid) against the counterfactual case in which the only two driving forces that are active when simulating the model are the capital tax rates and the government spending shares while the remaining two driving forces are set equal to their steady state levels ("fiscal policy only," red/marker). Both plots also present the simulated series using the calibrated benchmark neoclassical model when all four driving forces are used ("benchmark," red/dashed). Sources: World Bank's WDI and authors' calculations.

Lastly, we can also uncover the reasons why the model-generated saving rate diverges from the data after 2005. In the data, the saving rate hovers around 20% between 2005 and 2010. Yet, in the model, the saving rate declines during this period. The reason for this decline appears to be the path of the TFP factor growth rate used in the simulations.

We conclude that both the changes in the TFP factor growth rate and changes in fiscal policy that allowed for a large decline in the tax rate in 1987 play an important role in shaping the time path of the saving rate in Chile. The relative importance of these two factors, however, is different in different time periods.

4.2.2 Colombia

The saving rate in Colombia fluctuates around 18% from 1970 to 1994, declines to 13% between 1995 and 2001, and fully recovers by 2010. Two driving forces go through major changes in this period. First, there is a decline in the TFP growth rate after 1995. The average TFP growth rate between 1970 and 1995 is 1.34%. Starting in 1996, the TFP growth rate declines to around zero. In fact, the average TFP growth rate between 1996 and 2000 is 0%. After 2002, the TFP growth rate recovers to generate an average growth rate of 1.8 percent between 2002 and 2010. The second development, in the mid-1990s, is the large increase in the share of government expenditures in GNP accompanied by an

increase in taxes as displayed in Figure 2. This ratio increases from roughly 10% throughout the early 1990s to 23% in 1999 while the tax rate increases from around 3% until 1990 to around 10% in mid-2000s.

Figure 6: Saving Rate in Colombia: Counterfactual Experiments

Note: The left plot compares the observed gross national saving rate in Colombia ("data," blue/solid) against the counterfactual case in which the only driving force that is active when simulating the model is the TFP growth rate and the remaining three driving forces are set equal to their steady state levels ("TFP only," red/dashed). The right plot compares the observed gross national saving rate in Colombia ("data," blaue/solid) against the counterfactual case in which the only two driving forces that are active when simulating the model are the capital tax rates and the government spending shares while the remaining two driving forces are set equal to their steady state levels ("fiscal policy only," red/marker). Both plots also present the simulated series using the calibrated benchmark neoclassical model when all four driving forces are used ("benchmark," red/dashed). Sources: World Bank's WDI and authors' calculations.

In the next two counterfactual experiments, we isolate the impact of TFP growth versus fiscal policy on the time path of the saving rate. The left panel in Figure 6 displays the saving rate in the counterfactual experiment where we only feed in the time series path of the TFP growth rate. Notice that the saving rate generated in this experiment is similar to the benchmark case except for certain periods. In particular, this counterfactual does not capture the decline in the saving rate that occurs in the data in 1996. The counterfactual experiment that is depicted in the right panel of Figure 6 where the exogenous path of taxes and G/Y are included is, however, better able to capture the decline in the saving rate in the 1990s. In this "fiscal policy only" experiment, the saving rate actually starts declining earlier than in the data.

As in the case of Chile, one conclusion that can be drawn from these two experiments is that both factors play a role in the decline of the saving rate between 1995 and 2001, while the behavior in the years before appears mostly driven by TFP growth. The increase in the size of the government in the 1990s results in the sharp decline in the saving rate early in this episode while the low TFP growth rate prolongs the decline in the saving rate

into 2001. The recovery observed in the saving rate by 2010, however, seems to be mostly accounted for by the TFP growth rate. In the second counterfactual experiment "fiscal policy only," the saving rate remains stable after year 2000. In the "TFP only" experiment, the saving rate gradually increases to around 18% in 2010, similar to what is observed in the data.

4.3 Comparisons across Countries

The analyses conducted so far identifies the TFP growth rate and the fiscal policy as playing important and distinct roles in shaping the time path of the saving rates at different time periods in Colombia and Chile. In this section, we examine the extent to which these two factors may explain the differences in saving rates across these two countries. This exercise may be particularly interesting given the reversal in the saving rate between the two countries. Until the mid-1980s the saving rate in Colombia is higher than the saving rate in Chile. This is completely reversed after the mid-1980s and the saving rate in Chile remains much higher that that of Colombia until the end of the period analyzed.

4.3.1 Chile versus Colombia

In the left panel of Figure 7, we present the data for the saving rates in the two countries together. In the right panel, we present the results obtained from the benchmark model. The model mimics some of the similarities and the differences between the two countries rather well. In particular, the model is able to capture the initial low saving rates in Chile relative to Colombia, and the reversal in the saving rates of the two countries in 1988. The average saving rate before 1988 is 17.5% in Colombia and 11.4% in Chile. The model-generated average saving rates for this period are 19.6% and 14.6% for Colombia and Chile, respectively. For the period after 1988, the average saving rate in the data is 15.6% for Colombia and 22.7% for Chile, while the model generates an average saving rate of 14.6% and 24.3% for Colombia and Chile, respectively. These results are summarized in the first four columns of Table 2.

Next, we investigate the extent to which differences in TFP growth and/or fiscal policies between these countries might account for the reversal in their saving rates. Before 1989, annual TFP growth rates in Colombia and Chile are similar to each other with an average of 1.3% and 1.8% in the two countries between 1970 and 1988. From 1989 until 2010, however, the average TFP growth rate in Colombia declines to 0.9%, while it increases to

2.5% in Chile. In addition, tax rates and government expenditures decline dramatically in Chile in the mid-1980s, while they continue increasing in Colombia.

We examine to what extent the reversal in TFP growth rates and the changes in the path of fiscal policy might have impacted the reversal in their saving rates by running two counterfactual experiments. In the first one, we subject the Colombian economy to the Chilean TFP growth rate starting in 1989. The model economy otherwise is calibrated to the Colombian economy. The results are displayed in column "Exp. 1" in Table 2. The results reveal that the saving rate in Colombia would have been two percentage points higher, relative to the benchmark, after 1989 if Colombia had experienced the same TFP growth rate as in Chile (16.6% vs 14.6%). Nevertheless, the saving rate after 1989 would not have risen to the levels seen in Chile in this subperiod (22.7%). In the next experiment, we assume that tax rates and government expenditures as a percent of GDP in Colombia continue at their levels in 1988. The results are displayed in column "Exp. 2" where the saving rate in the 1989-2010 period increases by another percentage point (17.6).

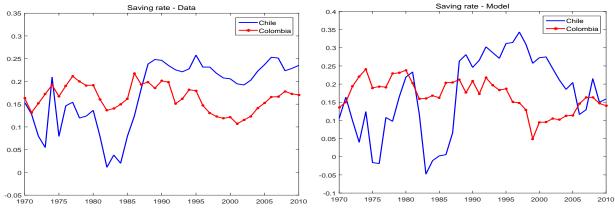

Figure 7: Saving Rate: Model and Data

Note: The left panel presents the observed gross national saving rates in Chile (blue/solid) and Colombia (red/marker). The right panel presents the simulated saving rates by the benchmark neoclassical model for these two countries when all four driving forces are active. Sources: World Bank's WDI and authors' calculations.

These experiments reveal that the decline in the TFP growth rate and the increase in the share of the government in Colombia both play a role in the decline in their saving rate in the second half of the sample. If these two factors had progressed in more favorable

 $^{^{16}}$ In the data, the capital income tax rate increases from 3.9% in 1988 to around 10% in the late 2000s. Government expenditures as a share of GDP also rise from 9% in the early 1980s to above 16% in the 2000s. In this experiment, we keep the tax rate at 3.9% and the government expenditure share at 9% after 1989.

Table 2: Saving Rate: Chile and Colombia

	Chile		Colombia		Counterfactuals	
	Data	Model	Data	Model	Exp 1.	Exp. 2
1970-1988	11.4	9.04	17.5	19.4	18.1	17.1
1989-2010	22.7	24.3	15.4	14.6	16.6	17.6

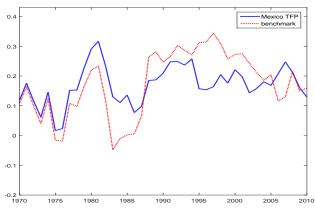

Note: The first four columns present observed and simulated GNS rates with the benchmark model. "Counterfactuals/Exp.1" presents simulated GNS rate with the benchmark model for Colombia when TFP growth rate is the one observed in Chile only for the 1989-2010 subperiod. "Counterfactuals/Exp.2" presents the simulated GNS rates with the benchmark model when TFP growth rate is the one observed in Chile only for the 1989-2010 subperiod, and tax rates and G/Y continue at their 1988 levels. Sources: World Bank's WDI and authors' calculations.

ways, the saving rate in Colombia would have been closer to the saving rate in Chile after 1989. The differences in their saving rates would not have been eliminated, however.

4.3.2 Chile versus Mexico

While the model's performance is much weaker for Mexico, there are interesting insights that can be learned from the comparison between Mexico and Chile. There is a big difference between the saving rate behavior of these two countries in the late 1980s after they both reform their tax systems. Recall that in our benchmark exercise, effective capital tax rates drop from 56% to 11% in Chile and from 41% to 10% in Mexico. Yet, while the saving rate triples in Chile between 1985 and 1989, it actually declines in Mexico. This observation need not be puzzling in light of our findings. It turns out that the behavior of another factor that affects saving rates is very different between the two countries after the mid-1980s. Between 1983 and 2010, the average annual TFP growth rate in Mexico is -0.26%, while it is 1% in Chile. The difference in their performance is even more striking between 1983 and 1988. In Mexico, average TFP growth is -2.94%, while in Chile it is 4.38%. High productivity growth increases returns to capital, incentivizing higher savings.

Figure 8: Saving Rate in Chile

Note: Figure 8 presents the gross saving rate simulated by the calibrated benchmark model for Chile when all four driving forces are active ("benchmark," blue/solid). The red line with markers presents the counterfactual simulation for the Chilean gross saving rate when all four driving forces are active but TFP growth rate is identical to that of Mexico after 1983 ("Mexico TFP"). Sources: World Bank's WDI and authors' calculations

To examine the impact of the differences in the TFP growth rates between Chile and Mexico in affecting their saving rates, we conduct a counterfactual experiment where we subject Chile to the Mexican TFP growth rate after 1983. The saving rate labeled "Mexico TFP" in Figure 8 displays the saving rate in Chile for this hypothetical case. Notice that there would still have been an increase in the saving rate after the tax reform in Chile, but this increase would have been smaller and much shorter lived.

4.3.3 Latin America versus Asia

As documented above, saving rates in Latin America have been persistently lower than the saving rates in many Asian countries. For example, between 1970 and 2010, the average gross national saving rate in "Asia 5" (China, Korea, Singapore, Hong Kong, and Taiwan) was 35.5%, while the average saving rate for "Latin America 6" (Argentina, Brazil, Chile, Colombia, Mexico, and Peru) was 18.9%. During the same time period, the TFP growth rate in these countries were also markedly different. ¹⁷Figure 9 displays the growth rate of TFP for this set of countries since the 1970s. While a full-scale investigation to uncover the reasons for the differences in the saving rates between Asia and Latin America is beyond the scope of this paper, there is one particular question we can ask: To what extent

¹⁷To compute TFP series for the Asian countries we followed the same strategy as that used in the case of Mexico, Chile, and Colombia. That is, we use data on investment from the World Bank's WDI tables to construct a measure of the capital stock, using equation (1). We then adjust this capital stock by adding net foreign assets to obtain a measure of national capital. Finally, WDI data are also used for output (GNI) while the labor series come from the Conference Board Total Economy Database.

could differences in TFP growth rates between Latin America and Asia have influenced differences in their saving rates?

See text for further details on TFP growth rates. Source: World Bank's WDI and authors' calculations.

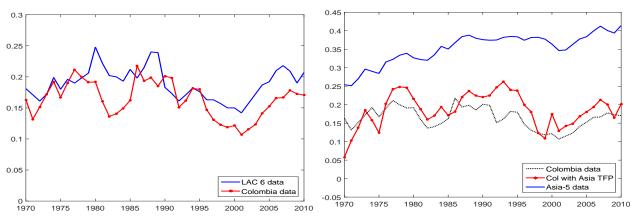

Figure 10: Saving Rate in Latin America, Colombia and Asia

Note: The left panel presents the simple average of observed gross national saving rates across six Latin American countries (LAC6) –Argentina, Brazil, Chile, Colombia, Mexico, and Peru– in solid/blue and Colombia alone in red with markers. The right panel presents the simple average of the gross national saving rates across five South East Asian countries ("Asia 5-Data," blue/solid) –China, Korea, Singapore, Hong Kong, and Taiwan– the observed gross national saving rate in Colombia ("Colombia data," black/dashed) and the counterfactual simulated series of gross national saving rate with the model calibrated to Colombia when all four driving forces are active and TFP growth rate is that of Asia-5. Source: World Bank's WDI and authors' calculations.

For this purpose, we take Colombia as a typical Latin American country and ask what would have happened to the saving rate in Colombia had it faced the same TFP growth rate as in "Asia 5" during this time period. We choose Colombia as a typical Latin American

Table 3: Saving Rate: Colombia with Asia TFP

			with Asia TFP
	Data	Model	COL 1
1970-2010	16.4	16.9	18.6
1970-1988	17.5	19.6	18.1
1989-2010	15.6	14.6	19.0

Note: The first two columns present the observed and simulated GNS rates with the benchmark model. Column "with Asia TFP/COL1" presents the simulated GNS rate from the model when all driving forces are active but TFP growth rate is coming from the simple average across five South East Asian countries. Sources: WDI and authors' calculations.

country because of the similarities between the saving rate in Colombia and the average saving rate of the group of six Latin American countries displayed in the left panel of Figure 10. This counterfactual experiment might allow us to generalize about the role of productivity growth –or the lack of it– in accounting for low saving rates in Latin America in general.

The right panel of Figure 10 displays the results for this counterfactual experiment, labeled "COL with Asia TFP", together with the data on saving rates in "Asia 5" and Colombia. In this experiment, we calibrate the model to Colombia, but use the average TFP growth rate observed in "Asia 5". Notice that the higher TFP growth rate does increase the saving rate in Colombia, especially in the 1990s. However, significant differences reamain with respect to the actual saving rate in "Asia 5." Table 3 summarizes the saving rates obtained in this experiment at different time periods. The impact of higher productivity growth is evident in the 1989-2010 period: while in the benchmark economy, the model-generated saving rate is 14.6% for this period, the one generated using the TFP growth rate from "Asia 5" is 19%. The average saving rate in "Asia 5" during this period, however, was 38%, leaving room for other factors to account for the differences between Asia and Latin America.¹⁸

5 Concluding Remarks

In this paper, we explore what accounts for the anemic saving rates in Latin America, and the extent to which they have been related to the forces that have shaped economic

¹⁸Detailed studies of the saving rates in China, for example, point to the role of income uncertainty, lack of comprehensive pension coverage, lack of long-term-care insurance, and the decline in family insurance due to the one-child policy as some of the explanations for the high saving rates in China (Imrohoroglu and Zhao (2016)).

growth in the region. We build a one-sector, neoclassical growth model and calibrate it to a subset of Latin American economies: Chile, Colombia, and Mexico. A crucial element in our quantitative analysis is to use (and in some cases construct from primary sources) a time series of the forces that have driven economic growth on these countries for the past 40 years..

The main takeaway is the relatively good performance of the model in terms of its ability to account for both the level as well as the broad dynamics of the saving rates observed during this period of analysis, particularly in the cases of Chile and Colombia. Furthermore, we reach a number of conclusions based on our counterfactual experiments. First, both for Chile and Colombia, changes in the TFP growth rate together with the changes in the tax rates and the size of the government have played an important role in shaping the changes in their saving rates. For Chile, the timing of the increase in the saving rate in the mid-1980s is affected more by the tax reforms than the growth rate of TFP. For Colombia, the decline in the saving rate in the mid-1990s seems to be due to a combination of the decline in the growth rate of TFP and the increase in the tax rate. In fact, these two factors are capable of generating the reversal of the saving rates in the two countries in the mid-1980s. We also find that high TFP growth rates observed in the Asian countries would not have been capable of generating similarly high saving rates in Latin America. Our counterfactual experiments indicate that the higher TFP growth rate experienced in the Asian countries during the 1989-2010 period could have increased the saving rate by almost five percentage points in Latin America. While this is not a trivial increase, it still falls short of filling the gap with respect to the high saving rate observed in the Asian countries.

A Appendix

A.1 Data Sources and Methods

To construct the capital stock series we use data on gross fixed capital formation and changes in inventories from national sources, which are virtually identical to those reported in the WDI, along with a constant depreciation of 3.5% in all cases. We use these data to iterate equation (1) starting from an initial capital value. To obtain the latter, we use an initial capital to output ratio and multiply by constant prices GDP (from WDI). For Mexico, this initial value corresponds to the capital-to-output ratio for 1970 in Kehoe and Meza (2011) of 1.48, which is very close to the 1.51 found in Bergoeing et al. (2002). For Chile, the 1970 capital-to-output ratio (2.69) is taken from DIPRES (2016), while for Colombia (2.76), it is taken from GRECO (2002). Once we have a series for total capital, we add net foreign assets (NFA) in constant prices, which in turn is obtained by deflating current prices NFA from Lane and Milesi-Ferretti (2007) using the investment deflator from WDI. The resulting measure of capital is used, along with data on gross national product from WDI and equation to obtain our closed economy TFP series.

Our labor input series is obtained by dividing total weekly hours worked from the Conference Board Total Economy Database into working age population from WDI. To calibrate the labor disutility parameter, we use the period average for this labor input series and for consumption and output from WDI in the steady state version of the labor supply equation:

 $\alpha = (1 - \theta) \frac{(T - h)}{h} \frac{y}{c}$

For the years in which effective capital tax rates can be constructed (Colombia 1970-2010; Chile 1996-2010; Mexico 1993-2010) we followed Mendoza, Razin, and Tesar (1994). Formally we define:

$$\tau = \frac{\tau_h(OSPUE + PEI) + TIPC + RTIP + TFCT}{OS} \tag{3}$$

$$\tau_h = \frac{TIPCIH}{OSPUE + PEI + W} \tag{4}$$

where τ_h is the effective tax rate paid by households; OSPUE is unincorporated business net income; PEI is interest, dividends, and investment receipts; TICPIH is taxes on income, profits, and capital gains paid by households; W corresponds to wages and salaries of dependent employees; TICP is taxes on income, profits, and capital gains paid by corporations; RTIP is recurrent taxes on immovable property; OS is net operating surplus of the overall economy, and TFCT is taxes on financial and capital transactions. In Colombia, all of these series are taken from the national statistics office (DANE). For Chile, the data are taken from the OECD's Revenue Statistics dataset for variables in numerator of equations (3)-(4) and National Accounts dataset for variables in the denominator. For Mexico, we use the actual rates reported in Anton-Sarabia (2005) for 1993-2001 and update them using, again, series from OECD and equations (3)-(4).

As in previous studies (e.g., Bergoeing et al., 2002), we assume that the tax reforms in Mexico and Chile were rather unexpected. To incorporate this into our framework, we simulate the model economy for the full period and let it converge to the steady state using the pre-reform (higher) tax rate for all years (and for the steady state). Then we simulate the model again starting in 1988 with the actual post-reform tax rates, i.e., we "surprise" agents with a tax reform.

Our series of the share of government in output is found by dividing government consumption into GNP (both from WDI). Population growth is simply the annual growth of working age population (also from WDI).

The full data series can be found at the end of this Appendix.

A.2 Additional Counterfactuals

Below we present two additional sets of counterfactuals not presented in the main text. In the first of these exercises we turn off all the driving forces except for population growth. The results can be seen in Figure 11.

Colombia: Population growth only

Figure 11: Additional Counterfactuals: Population only

Note: These plots compare the observed gross national saving rate in Colombia ("data," blue/solid) against the counterfactual case in which the only active force is population growth. Sources: World Bank's WDI and authors' calculations.

The last set of counterfactuals replicate the exercises of sections (4.2.1) and (4.2.2) for the case of Mexico. The left panel of Figure 12 displays the counterfactual experiment where only the time series data for the TFP growth rate are used in the simulations. Notice that this case generates even larger fluctuations than the benchmark economy. Therefore, the excess volatility generated in the benchmark simulations summarized in Figure 3 is likely due to the impact of the TFP growth rate that is used in the model. In the right panel where we feed in only the change in the tax rate and G/Y that take place in Mexico, the model generates very smooth saving rates that indeed increase due to the decline in the tax rates in 1986.

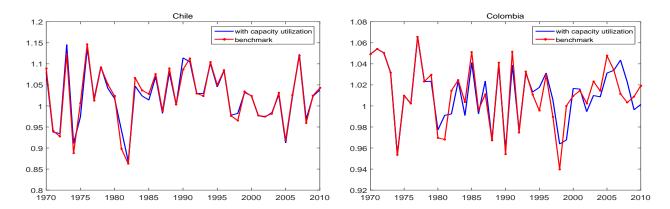

Figure 12: Saving Rate in Mexico: Counterfactual Experiments

Note: The left plot compares the observed gross national saving rate in Mexico ("data," blue/solid) against the counterfactual case in which the only driving force that is active when simulating the model is the TFP growth rate and the remaining three driving forces are set equal to their steady state levels ("TFP only," red/dashed). The right plot compares the observed gross national saving rate in Mexico ("data," blue/solid) against the counterfactual case in which the only two driving forces that are active when simulating the model are the capital tax rates and the government spending shares while the remaining two driving forces are set equal to their steady state levels ("fiscal policy only", red/marker). Both plots present also the simulated series using the calibrated benchmark neoclassical model when all four driving forces are used ("benchmark," red/dashed). Sources: World Bank's WDI and authors' calculations.

A.3 Capacity Utilization

Finally, the figures below present the times series for TFP growth rate for Chile and Colombia for the cases where capital is not adjusted for capacity utilization (benchmark) and when it is (robustness) in the two countries of the three (and years) that we study for which data on capital capacity utilization rates exist: Chile (1970-2010) and Colombia (1980-2010). Results are strongly robust when one does account for this additional dimension. Indeed, TFP growth rates with and without capacity utilization rates are strongly correlated in both Chile (0.98) and Colombia (0.85) for the subperiods mentioned above.13.

Figure 13: TFP with and without Capacity Utilization

Note: The TFP series are computed by pre-multiplying the capital stock (after NFA adjustments) by the capacity utilization index. For Chile the source for the utilization series is DIPRES (2016), while for Colombia the series are obtained from Fedesarrollo's Enterprise Survey (http://www.fedesarrollo.org.co/encuestas/boletines-empresarial-eoe/).
