Abstract*

This paper studies volatility spillovers in credit default swaps (CDS) between the corporate sectors and Latin American countries. Daily data from October 14, 2006, to August 23, 2021, are employed. Spillovers are computed both for the raw data and for filtered series which factor out the effect of global common factors on the various CDS series. Results indicate that most spillovers occur within groups—that is, within the series of sovereign CDS contracts and the price contracts of CDS issued by global corporations. However, considerable spillovers are also registered between LAC sovereigns and corporations. Interesting differences are encountered between filtered and unfiltered data. Specifically, spillovers from countries to corporations are overestimated (by about 4.3 percentage points) and spillovers from corporations to sovereigns are underestimated (by about 5.8 percentage points) when unfiltered data are used. This result calls for a revision of results obtained from studies that do not consider the role played by global common factors in system spillovers. Like in most related studies, spillovers show considerable time variation, being larger during times of financial or economic distress. When looking at total system spillovers over time, those corresponding to unfiltered series are always larger than those corresponding to filtered series. The difference between the two time series is largest in times of distress, indicating that global factors play a major role in times of crisis. Similar conclusions are derived from network analysis.

1. Introduction

International financial market integration has increased considerably over the last two decades. Factors that have contributed to this observed globalization include the implementation of policies favoring financial market deregulation, the development of new trading technologies, and the interest of global investors in diversifying their financial portfolios in world asset markets. Financial integration can potentially yield many benefits for market participants and even for countries. For instance, it helps achieve more investment opportunities and better chances for risk sharing, which stimulates financial market deepening. This in turn increases economic stability and resilience (Bekaert et al. 2006; Uribe and Chuliá, 2021). However, the benefits of financial integration are not cost-free. In a more financially integrated world, national policies and relevant financial events may have important cross-border effects.

Bernanke (2005) drew the attention of the profession almost two decades ago to the complex relationship between debt committed by global corporations and both debt issuances and government debt portfolio holdings of emerging economies' governments. Bernanke points out that, in emerging countries, the government may act as a financial intermediary between the citizens of these countries and the international private debt markets used by global corporations to fund their operations. We study the close relationship between emerging public and global private debt markets that enable the emergence of risk spillovers in both directions, from corporates to emerging sovereigns and from emerging sovereigns to global corporations, which has been largely overlooked in the literature.

Figure 1 shows recent trajectories of credit default swaps (CDS) since 2006, for five large corporations and four emerging economies in Latin America. Currently one of the most indebted regions in the world, Latin America shares strong historical commercial and financial ties with the United States, where most of these global corporations operate. CDS spreads are timely indicators of the dynamics of corporate and sovereign debt markets. They offer the opportunity to track risk spillovers in real time, which is not possible via traditional analyses that focus on financial statements and national account statistics.

Figure 1. Credit Default Swaps for Selected Corporations and Emerging Economy Governments, October 2006 to August 2021

Note: Selected CDS series for five corporations and four emerging sovereigns in Latin America.
Source: Bloomberg.

Figure 1 shows that the two markets (i.e., emerging sovereigns in Latin America and corporate global) are closely linked. Series coming from the corporate sector and from sovereign markets are practically indistinguishable, as they all peak around the same events—the Global Financial Crisis, the European Crisis, and COVID-19—albeit with different intensities. The figure raises many questions: What part of this close relationship is due to global factors that affect both markets simultaneously? What part is due to cross-spillovers between these specific markets? How strong is the relationship between and within these two markets? Do shocks originate in the emerging sovereign debt market or in the corporate global market? Have the strength and shape of the relationship changed in recent decades, especially in times of crisis? By answering these questions, this study contributes to the literature on international finance that is concerned with financial vulnerability and financial stability arising from the complex relationship between public and private global debt markets. It also adds to the corporate finance literature that emphasizes the unique features of CDS contracts to extract market information and timely signals about the price of risk in debt markets.¹ More generally, we add to the large and growing literature on financial contagion and volatility transmission in financial markets (e.g., Aït-Sahalia et al., 2015; Bradley and Taqqu, 2004; Caccioli et al., 2014; Chuliá et al. 2018; Diebold and Yilmaz, 2009; Forbes and

¹ See in this literature recent examples by Lee et al. (2017), Norden (2017), Oehmke and Zawadowski (2017), Siriwardane (2019) and Tang and Yan (2017).

Rigobon, 2002; Gamba-Santamaria et al., 2017), but unlike most of this literature, we focus on debt markets.

We construct time-varying indices of the price of risk in sovereign and corporate debt markets based on more than 600 daily series of corporate CDS and 48 series of sovereign CDS from October 14, 2006, to August 23, 2021, following Josee and Husson (2013) methodology. Moreover, the paper estimates risk spillovers and connectedness indicators (Diebold and Yilmaz, 2009, 2012). Many recent studies have followed Diebold and Yilmaz's approach for estimating volatility spillovers within many different markets. However, some recent studies have challenged the construction of spillover indices using "raw" data without considering the role that common factors may play in spillover transmission (see, for instance, Guerello and Tronzano, 2020; Ha et al., 2020, among others). Omitting the role of common factors may lead to the magnification of true volatility spillovers within markets. Therefore, our estimations control for factoring out unobserved common factors before applying the traditional Diebold-Yilmaz framework to the data.

It is not a trivial issue, since common factors that affect debt markets disregard their nature (i.e., private, or public, emerging or developed, etc.) before estimating spillover statistics for the globally integrated debt markets. The estimation results show that spillovers are considerably larger when the role of global common factors is ignored, as most papers in the literature do. Additionally, spillover directions and intensities change considerably when global financial factors are factored out before volatility spillovers are computed. The magnitude of spillovers under both scenarios differs most during periods of financial distress, indicating that global financial factors associated with financial uncertainty prevail among global common factors. We illustrate our results through network analysis for time series.

In general, most spillovers in the markets analyzed take place within groups, that is, within countries and within global corporations. However, considerable spillovers are also registered from Latin American sovereigns to global corporations and vice versa. As in most related studies, spillovers show considerable time variation, being larger during times of financial or economic distress. When looking at total system spillovers over time, those corresponding to raw series are always larger than those corresponding to the series that account for the global common factors. This indicates the overestimation of system spillovers that is produced when the effect of such global common factors is neglected. Indeed, the difference between the two time series is largest in times of distress, indicating that global factors play a major role during financial crises.

This paper is comprised of six sections. Section 2 is a literature review, which briefly discusses the nexus between corporate and sovereign debt markets, emphasizing the important nexus between global corporate debt and emerging market sovereign debt markets. This section shows why the assets under study are relevant. Sections 3 and 4 present the methodology and data used in this study. Section 5 presents the main results of our empirical analyses. Section 6 concludes.

2. Nexus between Corporate and Sovereign Debt Markets: A Review of the Literature

The literature agrees that sovereign and corporate debt spreads—which move alongside credit default swap (CDS) spreads—respond to some common macro factors. Hence, we can expect to observe strong co-movements between the two types of markets, and also across different national markets, which may be even larger in times of financial and economic distress. As highlighted by Dailami (2010), since corporate bonds are usually priced with respect to sovereign curves and, in turn, sovereign debt bears basically macroeconomic risks, there is a structural link between sovereign and corporate bonds. Lack of liquidity in specific markets, asset classes, or during crisis episodes can reinforce this link. The macro factors that underlie corporate and sovereign markets identified in the recent literature can be broadly summarized as: (i) monetary policy interventions and reference rates; (ii) global financial conditions, including policy and financial uncertainty, (iii) market-wide liquidity; (iv) the time-varying level of risk aversion and, to a lesser extent, (v) crude oil prices; and (vi) real estate prices.

The first and most commonly advocated factor underlying credit spreads is central bank policy interventions that affect both private and public debt markets. Krishnamurthy et al. (2018) examine the effects of the Securities Markets Programme, Outright Monetary Transactions, and Long-Term Refinancing Operations by the European Central Bank, on euro- and dollar- denominated sovereign bonds, corporate bonds, and corporate CDS rates. They document falling yields across countries after the implementation of these measures, especially in Italy, Spain, and Portugal, with a reduction in market segmentation that amounts to half of the total estimated effect. This is consistent with the findings of Zaghini (2017) for the corporate yield spreads, which use data from the Eurozone as well. Pancotto et al. (2019) quantify the impact of the European Bank Recovery Resolution Directive on the sovereign-bank nexus. Their main results show the lack of effectiveness of the measure in weakening the interconnectedness between sovereign and bank risks, since no significant effect is found in comparison with the corresponding effect on the control group of non-financial corporations. Nevertheless, their results still admit and, indeed, identify common factors leading the dynamics of all three sectors, financial and non-financial corporates, alongside sovereigns.

Another common shock that has been proposed is the global deterioration of financial conditions, and closely related to it, aggregate uncertainty, the level of risk aversion and market-wide liquidity in the financial markets. Zhu (2018) identifies shocks to the banking sector as the main driver of sovereign, banking, and corporate CDS spreads in 11 Eurozone countries from 2008 to 2013. Hui et al. (2013) study the role of funding liquidity, risk aversion, and equity market performance and find all of them to be crucial for the determination of financial, corporate, and sovereign risks in Europe. Calice et al. (2013) emphasize the role of liquidity as a main determinant of the interplay between different debt maturities and also across countries, during the global financial crisis, while Liu and Spencer (2013) point to investor confidence as a main factor underlying the cost of the debt for the corporate sector in emerging economies. Also regarding emerging markets, a remarkable study by Asis et al. (2021) provides evidence on the predictive power of U.S. interest rates, changes in global liquidity and risk aversion on corporate distress. Other studies, such as Wisniewski and Lambe (2015), Augustin (2018) and Wang et al. (2019), Shahzad et al. (2017), and Tang (2017), also document a significant effect of numerous macro-uncertainty and liquidity proxies on corporate and sovereign CDS

premiums across global debt markets. Finally, Hkiri et al. (2018) add crude oil to the equation, while Benbouzid et al. (2018) include real estate prices.

Regarding the direction of the shocks between the corporate and public sectors, most authors identify a unidirectional link from sovereign to corporate risk of default, and hence from sovereign to corporate spreads. Nevertheless, some important examples in the literature recognize complex and bidirectional interplays between the two markets, especially after considering the informational flows from financial institutions to sovereign markets, and in turn from corporations to banks.

A modern treatment of the subject in the former set of studies is Dailami (2010). Using a comprehensive database of emerging market corporate and sovereign entities from 1995 to 2009, he shows that investors' perception of sovereign debt turbulence results in larger costs of capital for private corporate issuers. Augustin et al. (2018) examine the transmission of sovereign to corporate credit risk using the Greek bailout on April 11, 2011, as a natural experiment. These authors estimated that a 10 percent increase in sovereign credit risk raises corporate credit risk by about 1.1 percent. The risk spillover from sovereign to corporate credit suggests the presence of a financial and a fiscal channel, because the authors find larger effects associated with firms that are directly dependent on banks or the government, while they find no support for indirect risk transmission through a deterioration of macroeconomic fundamentals. Mohapatra et al. (2018), employing a sample of 47 emerging markets and developing economies, examine the distance between sovereign credit ratings and the ratings assigned to new foreign-currency bonds issued by sub-sovereign entities (i.e., public sector enterprises, financial firms, and private non-financial corporations). Their results support stronger sovereign-corporate links between public sector enterprises and financial firms relative to the rest of the firms. Esteves and Jalles (2016) investigate the impact of sovereign defaults on the ability of corporations in emerging economies to fund their operations abroad. Using data from 1880 to 1913, their results confirm a large and persistent credit rationing phenomenon occurring after a sovereign default. Pianeselli and Zaghini (2014) and Hui et al. (2013) point to sovereign debt market turbulence as a primary determinant of the risk premium paid by non-financial corporations when issuing bonds or CDS contracts.

Gray and Malone (2012) and Yu (2017) adopt a more comprehensive perspective by modeling the spillovers and feedback effects between sovereign and banking sector risks. In their frameworks, risk spillovers between banks and sovereign markets may arise for three main reasons: bank holdings of risky sovereign debt, guarantees from sovereigns to banks in case of bankruptcy, and enlarged borrowing costs for banks as a consequence of widening sovereign spreads. Regarding the link between corporate debt and sovereign risk, Wu (2020) studies the role of dollarized corporate external debt in emerging countries and documents that an increase in foreign-currency corporate debt leads to an increase in the sovereign risk premium.

Even after considering the common factors that likely determine global debt markets, there is another possible channel that complements Bernanke's (2005) view, discussed in the introduction, by which private corporations, either financial or non-financial firms, may impact sovereign spreads or which can even explain spillovers between seemingly unrelated sovereign markets and corporate sectors of a foreign market. It corresponds

to a portfolio view of the transmission and has been scarcely explored by the literature. Hipper et al. (2019) document that such a channel may likely exist, since there are considerable diversification opportunities of adding corporate CDS indices to a traditional financial portfolio consisting of stock and sovereign bond indices. These authors emphasize that risk-diversification benefits mainly result from institutional investors replacing sovereign bonds (as opposed to stocks) by CDS. Both common macro factors and idiosyncratic risk spillovers motivate our study and methodological choices.

3. Methodology

In this section we review the methods used to construct the default indices on an industry level, and the global common factors that jointly determine the dynamics of CDS markets in both emerging and advanced economies. We also present the methodology to construct spillover and connectedness statistics between the corporate and sovereign sectors and to characterize the network structure of the CDS market.

a. Factor Estimation

The methodology used to construct the indices consists of two steps. In the first step we impute missing values in the original database using an iterative regularized principal component analysis (PCA) algorithm per Josse and Husson (2013). In the second, we use the complete data set to construct the sector indices and the global factors by traditional PCA. PCA analysis is a popular technique for dimensionality reduction and representation learning in artificial intelligence, and it is the most popular method in finance and macroeconomics to estimate factors in factor analysis of large data sets. Factor analysis seeks to encapsulate the time dynamics of large panels using a few common factors. While the general underlying dynamics are assumed to be the same for the whole system, idiosyncratic factor loads provide the way each series in the panel is related to the common time-varying factors. In particular, we use the first principal component to estimate the sector indices, which corresponds to a linear combination of the original series within each industry sector, with the weights of the linear combination obtained by an optimization process that maximizes the variance encapsulated in the index series.

Nevertheless, before using PCA it is preferable to impute any missing observations, instead of simply assuming that they are all equal to zero or to a constant term. Imputation should be ideally conducted in such a way that factors' estimation and imputation itself feed into each other, preventing the factor series from experiencing "jumps" when several individual CDS series appear in the database at the same time, as frequently occurs with CDS data. The way in which this interactive optimization is conducted is known as regularized PCA.

i. Regularized PCA

To estimate the sector factor indices, we use the method of regularized principal components, proposed by Josse and Husson (2013). In this methodology the objective is to determine a subspace that effectively reduces the distance between individual CDS and their projections. This is equivalent to finding two matrices labeled $F_{T \times S}$ and $U_{N \times S}$

with $S < T$ being the respective ranks, which provide the optimal approximation of the matrix constructed using the original dataset $X_{T \times N}$, where T refers to time and N to cross-sectional units (either individual CDS series for corporations or for countries). For this, we need to minimize the following criterion:

$$\vartheta = \|X - M - FU'\|^2 = \sum_{t=1}^T \sum_{n=1}^N \left(X_{tn} - m_n - \sum_{s=1}^S F_{ts} U_{ns} \right)^2, \quad (1)$$

M has dimensions $T \times K$ and each row equals $(m_1, \dots, m_N)$, that is, the vector with the mean of each variable. A common way to deal with missing values in traditional PCA is to ignore such missing values, and then to minimize the least-squares criterion in Equation 10 overall non-missing entries. An alternative way consists of minimizing the following criterion, by introducing a weighted matrix W , where $W_{tn} = 0$ if X_{tn} is missing or $W_{tn} = 1$ otherwise:

$$\vartheta = \sum_{t=1}^T \sum_{n=1}^N W_{tn} \left(X_{tn} - m_n - \sum_{s=1}^S F_{ts} U_{ns} \right)^2. \quad (2)$$

The iterative (regularized) PCA algorithm that minimizes (2) in the following steps:

- 1- Initial values such as the mean of each variable are used to replace missing values.
- 2- Regular PCA using the complete data set. Then, you impute the missing values with the reconstruction formulas (regularized). The number of components used for the imputation of missing data is calculated by cross-validation.
- 3- Steps are repeated 2-a) and 2-b) until convergence is achieved.

The output of the algorithm is used to estimate the sector indices in our application. In any case, the solution satisfies the following two Equations 3–4:

$$\hat{U}' = (\hat{F}'\hat{F})^{-1}\hat{F}'(X - \hat{M}), \quad (3)$$

$$\hat{F}' = (X - \hat{M})\hat{U}(\hat{U}'\hat{U})^{-1}. \quad (4)$$

Finally, the original CDS series were standardized to construct the variance-covariance matrix, before applying the PCA algorithms, so as to have unit variance and zero mean and facilitate comparison across series.

b. *Spillover Statistics*

The spillover indices were built upon the associated forecast error variance decomposition (FEVD) of a VAR representation with $N=20$ variables: 11 sector indices for global corporations, 1 corporate index for large firms with main operations in Latin American and Caribbean countries, and 8 country indices for the main markets in the region. We follow the traditional literature by Diebold and Yilmaz (2009, 2012) and provide both dynamic and static spillover analyses.

Note that before estimating the baseline VAR, we factor out the unobserved common variation from our 20 original series (and other 40 CDS series for sovereign CDS around the globe) as suggested by the recent econometrics literature (see, for example, Fan et al., 2021). The common variation is identified using the first 5 PC series of the 60 assets, which are subsequently used as regressors of the 20 original CDS in our database. To simplify notation, we will refer to the VAR system of factorized series as:

$$X_t = \Theta(L)\varepsilon_t, \quad (5)$$

$$X_t = \sum_{i=0}^{\infty} B_i \varepsilon_{t-i}, \quad (6)$$

where X_t is a matrix $T \times N$, $\Theta(L) = (I - \phi(L))^{-1}$, ε_t is a vector of independently and identically distributed errors with mean equal to zero, and Σ covariance matrix. $B_i = \phi B_{i-1} + \phi B_{i-2} + \dots + \phi B_{i-p}$ is the matrix of parameters, p is the number of lags included in the estimation, selected in our case according to the *Bayesian Information Criterion*, and T is the number of days. We also estimate spillover statistics using the unfiltered original series as a way of estimating the bias induced into the spillover statistics when global factors are not taken into consideration.

To estimate the FEVD from the h -step ahead forecast, we first need to identify the structural VAR innovations. As is traditional in this literature since Diebold and Yilmaz (2012), we follow Koop et al. (1996) and Pesaran and Shin (1998) to construct generalized VAR systems, and their associated generalized FEVD. Rambachan and Shephard (2021) analyze the conditions under which predictive time series estimands, such as the aforementioned impulse response, can be interpreted as a dynamic causal effect of assignments on outcomes, and show that indeed such conditions are considerably weaker than those required by traditional orthogonality conditions. This analysis is extendable to FEVD which are based on the same assumptions and provide further support to this popular methodological option, widely used in the literature to construct spillover statistics.

Following Diebold and Yilmaz (2012), the errors in the FEVD can be divided into *own variance* shares and *cross-variance* shares. The former are the portion of the errors associated with a shock to x_i on itself, while the latter are the fraction of the shocks on x_i associated with the rest of the variables in the system. The h -step ahead FEVD can be expressed as follows:

$$\theta_{ij}(H) = \frac{\sigma_{jj}^{-1} \sum_{h=0}^{H-1} (e_i' B_h \Sigma e_j)^2}{\sum_{h=0}^{H-1} (e_i' B_h \Sigma B_h' e_i)}, \quad (7)$$

where σ_{jj} is the standard deviation of the j -th equation, e_i is a selector vector that takes the value of one in the i -th element and it is zero otherwise. Naturally, Σ is the variance matrix of ε_t . To ensure that the sum of each row is 1, $\sum_{j=1}^N \tilde{\theta}_{ij}(H) = 1$, each entry of the variance decomposition must be normalized in the following way:

$$\tilde{\theta}_{ij}(H) = \frac{\theta_{ij}(H)}{\sum_{j=1}^N \theta_{ij}(H)}. \quad (8)$$

where $\sum_{i,j=1}^N \tilde{\theta}_{ij}(H) = N$.

After we have computed the normalized variance decomposition, a total spillover indicator can be estimated as:

$$C(H) = \frac{\sum_{i,j=1, i \neq j}^N \tilde{\theta}_{ij}(H)}{N} \times 100. \quad (9)$$

The indicator in the equation above measures the percentage variance that can be attributed to cross-spillovers. We can also construct a *directional spillover* index, according to which the effect of a shock from all other variables j on the variable x_i will be described by:

$$C_{i \leftarrow j}(H) = \frac{\sum_{j=1, i \neq j}^N \tilde{\theta}_{ij}(H)}{N} \times 100, \quad (10)$$

Analogously, the effect of a shock from x_i on all other CDS markets j will be given by:

$$C_{i \rightarrow j}(H) = \frac{\sum_{j=1, i \neq j}^N \tilde{\theta}_{ji}(H)}{N} \times 100, \quad (11)$$

Net spillover indicators can be constructed as follows:

$$C_i(H) = C_{i \rightarrow j}(H) - C_{i \leftarrow j}(H). \quad (12)$$

The type of indicators in the above equation measure the effect associated with a shock to variable x_i on the rest of the system variables.

c. Time Series Networks

We use the proposal by Barigozzi and Brownlees (2019) to estimate the network representation of our system of CDS. This methodology allows us to construct two different representations: (i) an adjacency matrix that defines the links between the CDS markets in our sample, by means of a conditional long-run correlation between any pair

of series, and it is an undirected network; and (ii) a Granger-causality approach, which establishes the edges (i.e., links) between the nodes in the (directed) network according to the existence of directional predictability between any pairs of series in the sample.

Formally, we can consider the autoregressive representation of the system described in equations 5 and 6, which is given by:

$$X_t = \sum_{k=1}^p A_k X_{t-k} + e_t, \quad (13)$$

where $e_t \sim iid(0, C^{-1})$, A_k and C are $n \times n$ matrices. Barigozzi and Brownlees (2019) focus on the cases of sparse VAR systems, in which both A_k and the concentration matrix C are assumed to be sparse, with typical entrances a_{kij} and c_{ij} . Indeed, this is the right assumption because we are inducing sparsity via the factorization of common forces before estimating the CDS network.

Networks are useful to represent the interdependence structure of the time series in X_t . We can define a network by the graph $\mathcal{N} = (\mathcal{V}, \mathcal{E})$, where $\mathcal{V}$ represents a set of vertices or nodes and $\mathcal{E}$ is the set of edges or links. Barigozzi and Brownlees (2019) propose two ways to measure interdependence in the network, in a traditional Granger causality sense and via estimation of long-run variance-covariance matrices for the system. In the former case, we have that x_{jt} Granger causes x_{it} if adding x_{jt} as predictor improves the mean square forecast error of x_{it+k} for any $k > 0$. We say that if $a_{kij} = 0$ for all k , then x_{jt} does not Granger cause x_{it} . Thus, a Granger network is defined as a directed network $\mathcal{N}_G = (\mathcal{V}, \mathcal{E}_G)$, where the presence of an edge from i to j means that i Granger causes j , i.e., $\mathcal{E}_G = \{(i, j) \in \mathcal{V} \times \mathcal{V} : a_{kij} \neq 0, \text{ for at least one } k \in \{1, \dots, p\}\}$. On its side, the contemporaneous network is defined as an undirected network $\mathcal{N}_C = (\mathcal{V}, \mathcal{E}_C)$, where a link between i and j denotes that both are partially correlated $\mathcal{E}_C = \{(i, j) \in \mathcal{V} \times \mathcal{V} : \rho_L^{ij} \neq 0\}$, where ρ_L^{ij} is the coefficient of partial correlation, estimated based upon the long-run covariance matrix of the series. The long-run covariance is defined as follows:

$$K_L = \Sigma_L^{-1} = (I - \sum_{k=1}^p A'_k) C (I - \sum_{k=1}^p A_k), \quad (14)$$

where $\rho_L^{ij} = -\frac{k_{Lij}}{\sqrt{k_{Lii}k_{Ljj}}}$.

4. Data

We collect daily data on CDS from October 14 2006 to August 23 2021. Our database includes 608 corporate CDS and 48 sovereign CDS from emerging, frontier, and advanced economies. All information was retrieved from Bloomberg data services.

Corporate CDS are from large firms belonging to 11 economic sectors according to a general Standard and Poor's classification: Consumer discretionary - DISC (e.g., Amazon and McDonald's); consumer staples - STAP (e.g., Coca-Cola, Pepsi, Kellogg's); communications - COMM (e.g., AT&T, Warner); energy - ENG (e.g., Chevron, Exxon);

financials - FIN (e.g., Bank of America, Citigroup); healthcare - HEAL (e.g., Baxter, J&J, Pfizer); industrials - IND (e.g., 3M, Boeing, General Electric); materials - MAT (e.g., Air Products, Cemex); real estate - REST (e.g., American Tower, Equity Commonwealth); technology - TECH (e.g., Apple, Cisco, Intel, Xerox); and utilities - UTI (e.g., CMS Energy, Dominion Energy, PSEG Power).

Corporate CDS data are characterized by many missing values. Figure 2 graphically depicts them, splitting the sample into three subsamples: Oct 2006–Dec 2012, Dec 2012–Aug 2016, and Sep 2016–Aug 2021. As expected, missing values are more frequent at the beginning of the sample and significantly decline at the end of it.

Figure 2: Missing Values in Corporate CDS Data

Note: Number of missing values in the sample of corporates.

Source: Authors' elaboration.

The presence of the numerous missing values motivated us to focus only on the most liquid CDS series for global corporates to construct representative indices of industry categories. We balanced both the number of non-missing values from the beginning to the end of the sample, and the observed time variation of the CDS, which speaks to CDS contract liquidity, to select our sub-sample of analysis. We ended up using 109 corporate and 48 sovereign CDS to estimate the corporate indices and to construct the global common factors of debt. Moreover, we conducted our network analysis using only six Latin American markets as representative of emerging market economies, due again to data availability considerations and a perceived greater variation of these CDS contracts from the beginning to the end of the sample, compared to other emerging market economies. From an economic point of view, Latin America is one of the most indebted regions in the world and it has been particularly impacted by the COVID-19 crisis (Franz, 2020; IMF, 2021). Also, it has strong commercial and financial ties with North America, where most of the 109 corporations used in our empirical analysis operate. This still high number of series keeps us from showing summary statistics of the original data. The

evolution of the constructed index and the global common factors in debt markets are presented in the results section. A list of the corporations included in our estimations is provided in the Appendix.

5. Results

This paper studies the nexus between corporate and sovereign debt markets from Latin American countries following the volatility spillover approach. To show the importance of seriously considering the role of global common factors, we compute spillovers for two distinct scenarios. Under the first, we factor out common global factors before performing spillover and network analyses. Under the second scenario, we compute spillovers and perform network analyses to the raw data, following the most traditional approach in this strand of the literature. We compare results under these two scenarios to show the important role that global common factors play, especially during times of financial turmoil.

5.1 Corporate Indices and Global CDS Factors

As mentioned before, the large number of corporate CDS series combined with the also large number of missing values led us to work with corporate sector indices, shown in Figure 3. Sector indices were constructed for the 11 sectors shown in the data section. These indices were constructed using only 109 firms for which CDS information contained only a few numbers of missing observations. We also constructed an index for LATAM corporate sector consisting of information for very large corporations in this region: Televisa, Telmex, Univision, Petrobras, Pemex, Cemex, and Codelco. This index is presented in Figure 4. The reason for studying the index is that we aim to consider in our estimations of spillovers the direct effect of companies operating in the region of study, and to observe whether the documented spillover between the price of global companies' debt and sovereign debt of emerging markets in LA survive after controlling for this direct linkage.

To construct the indices, in the two cases, we used an interactive procedure based on the Expectation Maximization algorithm combined with Principal Components Analysis, due to Josse and Husson (2013) and implemented by Josse and Husson (2016) in the statistical software R, to impute the missing data before we carried out our factor estimation. This reduces the possibility of inducing spurious correlations in the variance-covariance matrix, when several series appear simultaneously in the database.

Figure 4: Time Series Behavior of the Corporate LATAM Index

Note: CDS index for six Latin America Corporations.

Source: Bloomberg.

Note that CDS indices (11 sectors and LATAM) show similar time-series patterns. For instance, peaks are observed around the global financial crisis of 2008–2010, the European debt crisis of 2013–2015, and the COVID-19 crisis (2020). However, interestingly, while for the 11 sectors the highest peaks occurred around the global financial crisis, the LATAM index shows similar peaks in the three episodes of distress. This reflects the fact that Latin America was one of the regions most affected by the COVID-19 pandemic.

A well-known fact is that a relatively small number of international factors are important drivers of the behavior of financial markets worldwide. Dynamic factor models, global VAR models, panel-VAR models, and others are all constructed to reflect this observation. To properly identify market spillovers using our data and avoid confounding them with global unobservable factor movements, we estimate a few global factors that explain a large percentage of common variation in our selected time series. We factor out these common variations from our data and use residual information for estimating dynamic spillovers between the selected time series. While various ways for estimating global factors exist, we use PCAs on our complete database for their estimation. We chose the first five factors, explaining together over 90 percent of total variance. Figure 5 depicts these five factors.

Figure 5: Global Factors

a. *Networks And Connectedness Considering Global Factors and Without Considering Them*

Figure 6 Shows That Correlations Between The Sample Time Series Are Substantially Different When The Original Series Are Used As When The Residual Series Are Used. Hence, Studies Using Series That Do Not Account For These Common Factors May Have Misleading Results. In Other Words, Correlations Between The Original Series Are Likely Driven By Commonly Omitted Causes That Should Be considered When Constructing The Network. Such Common Causes May Be Even Transversal To All Financial Markets, Instead Of Being Specific To Debt Markets.

Figure 6: Estimated Correlations When Original (Left) And Residual (Right) Series Are Used

Note: Correlation matrix between original series (left) and filtered series (right) using the five macro factors presented in figure 5 in individual regressions.

Source: Authors' calculations.

System spillovers are presented in Table 1. Panel A presents spillovers computed following the method proposed by Diebold and Yilmaz (2009, 2012), applied to the residual series computed after factoring out the five main common factors.

Spillovers are particularly large between global corporate sectors. Specifically, 48.5 percent of total system spillovers are registered between global corporate CDS, including LATAM corporate, which have access to international debt markets (box on the top left of Table 1, Panel A). Sovereign debt spillovers in Latin America countries go in second place, accounting for 28.5 percent of total spillovers (box on the top right of Table 1, Panel A). Interestingly, spillovers of sovereigns in Latin America to global corporates and spillovers from corporates to sovereigns are of an almost identical magnitude, rounded to 11.5 percent of total spillovers each. This result indicates the importance of global portfolio rebalancing when risk aversion rises. Finally, spillovers from global corporate LATAM to sovereigns are almost negligible, ranging from 0.2 percent in the case of Argentina to a maximum of 3.3 percent in the case of Brazil, which represents a modest 0.5 percent of total spillovers.

Table 1, Panel B, shows spillovers computed to the raw data, that is, without factoring out common global factors. Results differ from those shown in Table 1, Panel A. Specifically, while spillovers within sectors are lower (44.2 percent, compared to 48.5 percent), spillovers within Latin American countries' sovereign CDS increase importantly (34.3 percent, compared to 28.5 percent). Total spillovers from countries to sectors are larger (15.8 percent vs. 11.5 percent), while spillovers from the corporate sector to sovereigns decrease importantly (5.7 percent vs. 11.5 percent). These results highlight the importance of considering global factors explicitly. When their role is ignored, the composition of total spillovers changes considerably. For instance, in our study using the raw data will lead to overstating spillovers within countries and from countries to the corporate sector, while will also lead to underestimating total spillovers from the corporate sector to Latin American countries.

Source: Authors' calculations.

Results are also sensitive to the definition of the sample period. To illustrate this point, we estimated total spillover indices for two sub-periods, one corresponding to the global financial crisis and other corresponding to the COVID-19 Crisis. Table 2 presents a comparison of results for the total sample and the two subsamples when the residual series is used. Note that spillovers within sectors represent a higher share of total spillovers for the full sample than during the two periods of financial and economic distress. This result indicates that spillovers within sectors are more important during normal times than during periods of distress. Similarly, spillovers within countries are greater during normal times. Conversely, spillovers from countries to the corporate sector and from the corporate sector to countries represent a larger share of total spillovers during times of financial and economic distress. This result shows that risk diversification opportunities between emerging market countries' assets and global corporate assets are significantly reduced when time goes bad. This may occur due to the balance rebalancing of global investor portfolios, which move from unsafe assets to safer assets during moments of financial turbulence.

Table 2: Total Spillovers for Total Sample and Two Subsamples for Residual Series

	<i>Full Sample</i>	<i>GFC</i>	<i>COVID</i>
<i>Within sectors</i>	48.5	46.8	42.4
<i>From countries to sectors</i>	11.5	13.2	17.6
<i>From sectors to countries</i>	11.5	18.0	12.5
<i>Within countries</i>	28.5	22.0	27.5
<i>Total</i>	100.0	100.0	100.0

Source: Authors' calculations.

We go one step further and show that total system dynamic spillovers are considerably higher when the unfiltered (raw data) series is used than when filtered (residual) data are used (see Figure 7). Note that while the total spillover unfiltered series is above the total spillover filtered series for the whole sample period, differences between the two series are especially pronounced during periods of distress. For instance, the difference between these two series of dynamic spillovers increases importantly during The Global Financial Crisis and the COVID-19 crisis. This important result shows that global common factors are likely to be related to financial uncertainty and financial risk issues.

Figure 7: Comparing Dynamic Spillovers

Note: Dynamic spillover index using a window length of 1000 days, which roughly corresponds to four years of transactions. The black line corresponds to the system based upon the filtered CDS series, while the red line corresponds to the original system that ignores common factors.

Source: Authors' calculations.

Figure 8 uses information on the residual series and shows that spillovers vary considerably over time and are especially high during times of financial distress. Similar results have been encountered in past related studies. Interestingly, during the COVID-19 crisis, corporates tended to be net receivers, while sovereigns were net givers of volatility.

Figure 8: Dynamic Spillover Residual Seri

Note: dynamic net spillover index by industry sector and sovereign market, using a window length of 1000 days. A positive value means that the market is a net volatility transmitter in a given day.

Figure 9 shows networks estimated following the methodology by Barigozzi and Brownlees (2019). This methodology allows two types of adjacency matrices to be estimated to construct the market network. The first one is a contemporaneous network and the second is a predictive network. The former estimates partial correlation between any pair of series in the dataset, while the second uses the VAR representation of the system to figure out the predictive power of any pair of series on each other, after factoring out the intermediate linkages in the network. The network structure presented in Figure 9 not only considers the five global factors that we estimated in the first step of our procedure, but also any intermediate correlation that still remains in the system after the first factorization, before plotting the representation. In this way, we can ensure the statistical and economic significance of the remaining interconnectedness. As can be

observed in the figure, network analysis based on the long-run correlations of the system shows that the included markets are well integrated. In particular, the LATAM Corporate sector seems very connected to both sovereign debt markets in Latin America and the global corporate debt market in general. In addition, the Argentinian CDS market seems to be associated with global corporates, which emphasizes the portfolio view of global debt markets. All in all, global portfolio rebalancing seems to be at the core of spillovers in global and emerging sovereign debt markets.

Figure 9: Network Analysis

Note: Network graph for the contemporaneous estimation of a sparse VAR system of 12 corporate CDS and 6 Latin American Sovereign CDS.

Source: Authors' calculations.

Further information can be obtained from analyzing the adjacency matrix of the network presented in Figure 9 for the original series and for the filtered series, which consider common global macro factors. These two matrices are shown in Table 3, Panel A and B, for the filtered and raw data, respectively. Once again, we observe that using the unfiltered series overestimates the number of significant connections within the global debt markets. This can be quantified by counting the number of connections described by Table 3 within sectors, within countries, and between countries and sectors (the adjacency matrix of the contemporaneous network is symmetrical because it describes an undirected graph). In this case, the density of the network within sectors increases

from 33 percent to 86 percent, from 36 percent to 79 percent within countries, and from 19 percent to 67 percent between countries and corporates, comparing the network adjusted by common macro factors with the network that ignores them. The differences are notorious and corroborate the analysis based on the forecast error variance of the unrestricted VAR system.

Source: Authors' calculations.

Finally, we also estimate Granger-causality networks. No predictive causality is detected between any pair of time series. This is a very interesting result. It indicates that while high spillovers are found between the included series, none of these high spillovers imply a predictive causality effect.

6. Conclusions

We study the relationship between the corporate sector and Latin American country CDS markets, focusing on volatility spillovers. We use daily data on CDS from October 14, 2006, to August 23, 2021. Our database includes 608 corporate CDS and 48 sovereign CDS. We focus our main analysis on six Latin American sovereign debt contracts, and 109 corporates. We further summarize the corporate information in 12 corporate debt indices according to the 11 Standard & Poor's industry categories, and one additional index for large corporations operating in Latin America.

Spillovers are computed both for the raw data and for filtered series, which factor out the effect of global common factors on the various CDS used in this study. Various interesting results are found. First, most spillovers correspond to within-group spillovers, that is, within countries and within global corporations. However, there are also important spillovers from emerging market sovereigns to corporations and vice versa. Interesting differences are encountered between filtered and unfiltered data. Specifically, spillovers from countries to corporations are overestimated and spillovers from corporations to sovereigns are underestimated when unfiltered data are used. This result calls for a revision of results obtained from studies that do not consider the role of global common factors on system spillovers.

Like in most related studies, spillovers show considerable time variation, being larger during times of financial or economic distress. When looking at total system spillovers over time, those corresponding to unfiltered series are always larger than those corresponding to filtered series. This underscores once more the overestimation of system spillovers that is produced when the effect of global common factors is not excluded from the data. The difference between the two time series is largest in times of distress, indicating that global factors play a major role in times of crisis.

In summary, we emphasize the role of a portfolio view of corporate and sovereign debt as a likely explanation for the significant spillovers that we estimate even after controlling for global macro factors in the market, both from a traditional perspective using the forecast error variance decomposition of a traditional VAR system and a more recent perspective using sparse VAR systems for estimating the network.
